Abstract

Markarian 501 is a high-peaked BL Lacertae object and has undergone many major outburst since its discovery in 1996. As a part of the multiwavelength campaign, in the year 2009 this blazar was observed for 4.5 months from March 9 to August 1 and during the period April 17 to May 5 it was observed by both space and ground based observatories covering the entire electromagnetic spectrum. A very strong high energy γ -ray flare was observed on May 1 by Whipple telescope in the energy range 317 GeV to 5 TeV and the flux was about 10 times higher than the baseline flux. We use the photohadronic model complimented by the extragalactic background radiation (EBL) correction to this very high state flare and have shown that the EBL plays an important role in attenuating the very high energy flux even though Markarian 501 is in the local Universe.

I. INTRODUCTION

Blazars are a sub class of AGN and the dominant extra galactic population in gamma rays[1]. These objects show rapid variability in the entire electromagnetic spectrum and have non thermal spectra which implies that the observed photons originate within the highly relativistic jets oriented very close to the observers line of sight[2]. Due to the small viewing angle of the jet, it is possible to observe the strong relativistic effects, such as the boosting of the emitted power and a shortening of the characteristic time scales, as short as minutes[3, 4]. Thus these objects are important to study the energy extraction mechanisms from the central super-massive black hole, physical properties of the astrophysical jets, acceleration mechanisms of the charged particles in the jet and production of ultra high energy cosmic rays, very high energy γ -rays and neutrinos.

The spectral energy distribution (SED) of these blazars have a double peak structure in the $\nu - \nu F_\nu$ plane. The low energy peak corresponds to the synchrotron radiation from a population of relativistic electrons in the jet and the high energy peak believed to be due to the synchrotron self Compton (SSC) scattering of the high energy electrons with their self-produced synchrotron photon[5, 6]. Depending on the location of the first peak, blazars are often sub classified into low energy peaked blazars (LBLs) and high energy peaked blazars (HBLs)[7]. In LBLs, the first peak is in the near-infrared/optical energy range and the second peak is around GeV energy range. For HBLs, the first peak is in the UV or X-rays range and the second peak is in the GeV-TeV energy range. The above scenario is called leptonic model and is very successful in explaining the multi wavelength emission from blazars and FR I galaxies[8–11].

Flaring seems to be the major activity of the blazars which is unpredictable and switches between quiescent and active states involving different time scales. While in some blazars a strong temporal correlation between X-ray and multi-TeV γ -ray has been observed, outburst in some other have no low energy counterparts (orphan flaring)[12, 13] and explanation of such extreme activity needs to be addressed through different mechanisms. It is also very important to have simultaneous multiwavelength observation of the flaring period to constraint different theoretical models of emission in different energy regimes.

The TeV photons of the flare can interact with the background soft photons in the jet to produce e^+e^- pairs. However, production of the lepton pair within the jet depends on the

size of the emitting region and the photon density in it. Also the required target soft photon threshold energy $\epsilon_\gamma \geq 2m_e^2/E_\gamma$ is needed. It is observed that the jet medium is transparent to pair production where the optical depth is very small[14, 15]. Also the TeV photons on their way to Earth can interact with the extragalactic background light (EBL) to produce the lepton pair[16]. However, TeV photons from the sources in the cosmologically local Universe (low redshift sources) are believed to propagate unimpeded by the EBL, although the effect is found to be non negligible[14].

II. MARKARIAN 501

Markarian 501 (Mrk 501) (RA:251.46°, DEC:39.76°) is a HBL at a redshift of $z=0.034$ (local Universe) is one of the brightest extragalactic sources in X-ray/TeV sky[14]. It is also the second extragalactic object (after Markarian 421) identified as a very high energy (VHE) emitter by Whipple telescope in 1996. Since its discovery, the multiwavelength correlation of Mrk 501 have been studied intensively and during this period it has undergone many major outbursts on long time scales and rapid flares on short times scales mostly in the X-rays and TeV energies[17–24]. It has been observed that, during these outbursts, both the peaks have shifted to higher energies and during the most extreme case the synchrotron peak \sim keV range has shifted above 200 keV[1]. Due to the low sensitivity of the previous generation instruments, Mrk 501 was primarily observed in VHE band during the outbursts. However, later on it was observed in all the wave bands. In the year 2009, as a part of large scale multiwavelength campaign covering a period of 4.5 months (from March 9 to August 1, 2009), Mrk 501 was observed[25]. The scientific goal of this extended observation was to collect a simultaneous, complete multifrequency data set to test the current theoretical models of broadband blazar emission mechanism. Also this will help to understand the the origin of high energy emission from blazars and the physical mechanism responsible for the acceleration of the charged particles in the relativistic jets. Between April 17 to May 5, Mrk 501 was observed by both space and ground based observatories, covering the entire electromagnetic spectrum including even the variation in optical polarization[25]. A very strong VHE flare was detected first by Whipple telescope on May 1st and 1.5 hours later with VERITAS. Both these telescopes continued simultaneous observation of this VHE flare until the end of the night. The detected flux enhanced by a factor of ~ 10 than the average

baseline flux ($3.9 \times 10^{-11} \text{ ph cm}^{-2} \text{ s}^{-1}$). A dramatic increase in the flux by a factor ~ 4 in 25 minutes and a falling time of ~ 50 minutes was observed. The flux measured at lower energies before and after the VHE flare did not show any significant variation. But, *Swift*-XRT (in X-ray) and UVOT (in optical) did observe moderate flux variability[25]. Also both Whipple and VERITAS did observe statistically significant variation in VHE band. Using the one-zone SSC model, the average SED of this multiwavelength campaign of Mrk 501 is interpreted satisfactorily.

Our aim here is to use the photohadronic model of Sahu et al.[15, 26–29] and the EBL model of Dominguez et al.[30] to interpret the observed very strong VHE flare data of May 1. We found that this flare can be explained well with this model.

III. TEV FLARING MODEL

The photohadronic model of Sahu et al.[15, 28, 29] rely on the standard interpretation of the leptonic model to explain both, low and high energy peaks, by synchrotron and SSC photons respectively as in the case of any other AGNs and Blazars. Thereafter, it is proposed that the flaring occurs within a compact and confined volume of radius R'_f inside the blob of radius R'_b ($R'_f < R'_b$)[15] (henceforth ' implies the jet comoving frame). Both the internal and the external jets are moving with the same bulk Lorentz factor Γ and the Doppler factor \mathcal{D} as the blob (for blazars $\Gamma \simeq \mathcal{D}$). In normal situation within the jet, we consider the injected spectrum of the Fermi accelerated charged particles having a power-law spectrum $dN/dE \propto E^{-\alpha}$ with the power index $\alpha \geq 2$. But in the flaring region the injected proton spectrum is a power-law spectrum supplemented with an exponential decay factor and is given as

$$\frac{dN_p}{dE_p} \propto E_p^{-\alpha} e^{-E_p/E_{p,c}}. \quad (1)$$

Here the high energy proton has the cut-off energy $E_{p,c}$.

The high energy protons will interact in the flaring region where the comoving photon number density is $n'_{\gamma,f}$ to produce the Δ -resonance. Subsequently the Δ -resonance decays to charged and neutral pions and the further decay of neutral pions to TeV photons gives the multi-TeV SED. The $n'_{\gamma,f}$ is much higher than the rest of the blob n'_γ (non-flaring) i.e. $n'_{\gamma,f}(\epsilon_\gamma) \gg n'_\gamma(\epsilon_\gamma)$. There is no direct way to estimate the photon density in the inner jet region as it is hidden. For simplicity we assume the scaling behavior of the photon densities

in the inner and the outer jet region as

$$\frac{n'_{\gamma,f}(\epsilon_{\gamma_1})}{n'_{\gamma,f}(\epsilon_{\gamma_2})} \simeq \frac{n'_\gamma(\epsilon_{\gamma_1})}{n'_\gamma(\epsilon_{\gamma_2})}, \quad (2)$$

which assumes that the ratio of photon densities at two different background energies ϵ_{γ_1} and ϵ_{γ_2} in flaring and non-flaring states remains almost the same. While the photon density in the outer region can be calculated from the observed flux, using Eq. (2) we can express the $n'_{\gamma,f}$ in terms of n'_γ .

The π^0 -decay TeV photon energy E_γ and the target SSC photon energy ϵ_γ in the observer frame are related through,

$$E_\gamma \epsilon_\gamma \simeq 0.032 \frac{\mathcal{D}^2}{(1+z)^2} \text{ GeV}^2. \quad (3)$$

The observed TeV γ -ray energy and the proton energy E_p are related through

$$E_p = \frac{10\Gamma}{\mathcal{D}} E_\gamma \simeq 10 E_\gamma. \quad (4)$$

The optical depth of the Δ -resonance process in the inner jet region is given by

$$\tau_{p\gamma} = n'_{\gamma,f} \sigma_\Delta R'_f, \quad (5)$$

where the resonant cross section is $\sigma_\Delta \sim 5 \times 10^{-28} \text{ cm}^2$. The efficiency of the $p\gamma$ process depends on the physical conditions of the interaction region, such as the size, the distance from the base of the jet, the photon density and their distribution in the region of interest.

In the inner region we compare the dynamical time scale $t'_d = R'_f$ with the $p\gamma$ interaction time scale $t'_{p\gamma} = (n'_{\gamma,f} \sigma_\Delta K_{p\gamma})^{-1}$ to constraint the seed photon density so that multi-TeV photons can be produced. For a moderate efficiency of this process, we can assume $t'_{p\gamma} > t'_d$ and this gives $\tau_{p\gamma} < 2$, where the inelasticity parameter is assigned the usual value of $K_{p\gamma} = 0.5$. Also by assuming the Eddington luminosity is equally shared by the jet and the counter jet, the luminosity within the inner region for a seed photon energy ϵ'_γ will satisfy $(4\pi n'_{\gamma,f} R'_f \epsilon'_\gamma) \ll L_{Edd}/2$. This puts an upper limit on the seed photon density as

$$n'_{\gamma,f} \ll \frac{L_{Edd}}{8\pi R'^2_f \epsilon'_\gamma}. \quad (6)$$

From Eq.(6) we can estimate the photon density in this region. In terms of SSC photon energy and its luminosity, the photon number density n'_γ is expressed as

$$n'_\gamma(\epsilon_\gamma) = \eta \frac{L_{\gamma,SSC}(1+z)}{\mathcal{D}^{2+\kappa} 4\pi R'^2_b \epsilon_\gamma}, \quad (7)$$

where η is the efficiency of SSC process and κ describes whether the jet is continuous ($\kappa = 0$) or discrete ($\kappa = 1$). In this work we take $\eta = 1$ for 100% efficiency. The SSC photon luminosity is expressed in terms of the observed flux ($\Phi_{SSC}(\epsilon_\gamma) = \epsilon_\gamma^2 dN_\gamma/d\epsilon_\gamma$) and is given by

$$L_{\gamma,SSC} = \frac{4\pi d_L^2 \Phi_{SSC}(\epsilon_\gamma)}{(1+z)^2}. \quad (8)$$

Using the Eqs. (7) and (8) we can simplify the ratio of photon densities given in Eq.(2) to

$$\frac{n'_\gamma(\epsilon_{\gamma_1})}{n'_\gamma(\epsilon_{\gamma_2})} = \frac{\Phi_{SSC}(\epsilon_{\gamma_1}) E_{\gamma_1}}{\Phi_{SSC}(\epsilon_{\gamma_2}) E_{\gamma_2}}. \quad (9)$$

The γ -ray flux from the π^0 decay is deduced to be

$$F_\gamma(E_\gamma) \equiv E_\gamma^2 \frac{dN(E_\gamma)}{dE_\gamma} \propto E_p^2 \frac{dN(E_p)}{dE_p} n'_{\gamma,f}. \quad (10)$$

The exponential factor in the power spectrum in Eq. (1) is responsible for the decay of the VHE flux, and falls faster for $E_\gamma > E_c$. Here E_c is the γ -ray cut-off energy corresponding to $E_{p,c}$. The EBL effect also attenuates the VHE flux by a factor of $e^{-\tau_{\gamma\gamma}}$, where $\tau_{\gamma\gamma}$ is the optical depth which depends on the energy of the propagating VHE γ -ray and the redshift z of the source. So there is a competition between the exponential cut-off and the EBL effect. It is well known that for intermediate and large redshift objects, EBL plays a dominant role in depleting the multi-TeV flux. However, for objects in the local Universe (e.g. Mrk 421 and Mrk 501), it may not be important, although the multi-TeV flare data of Mrk 501 observed by MAGIC and VERITAS telescopes were corrected for EBL effect. A 6 TeV photon was observed during the 4.5 months campaign and the attenuation factor $e^{-\tau_{\gamma\gamma}}$ for this photon is about .4 – 0.5 which is not negligible[14]. So here we would like to study the effect of EBL on the strongest VHE flare of May 1 and compare with the exponential cut-off scenario.

Including the EBL effect, the relation between observed flux F_γ and the intrinsic flux F_{int} is given as

$$F_\gamma(E_\gamma) = F_{int}(E_\gamma) e^{-\tau_{\gamma\gamma}(E_\gamma, z)}. \quad (11)$$

Then the EBL corrected observed multi-TeV photon flux from π^0 -decay at two different observed photon energies E_{γ_1} and E_{γ_2} can be expressed as

$$\frac{F_\gamma(E_{\gamma_1})}{F_\gamma(E_{\gamma_2})} = \frac{\Phi_{SSC}(\epsilon_{\gamma_1})}{\Phi_{SSC}(\epsilon_{\gamma_2})} \left(\frac{E_{\gamma_1}}{E_{\gamma_2}} \right)^{-\alpha+3} e^{-\tau_{\gamma\gamma}(E_{\gamma_1}, z) + \tau_{\gamma\gamma}(E_{\gamma_2}, z)}, \quad (12)$$

where we have used

$$\frac{E_{p1}}{E_{p2}} = \frac{E_{\gamma_1}}{E_{\gamma_2}}. \quad (13)$$

The Φ_{SSC} at different energies are calculated using the leptonic model. Here the multi-TeV flux is proportional to $E_\gamma^{-\alpha+3}$ and $\Phi_{SSC}(\epsilon_\gamma)$. In the photohadronic process ($p\gamma$), the multi-TeV photon flux is expressed as

$$F(E_\gamma) = A_\gamma \Phi_{SSC}(\epsilon_\gamma) \left(\frac{E_\gamma}{TeV} \right)^{-\alpha+3} e^{-\tau_{p\gamma}(E_\gamma, z)}. \quad (14)$$

Both ϵ_γ and E_γ satisfy the condition given in Eq.(3) and the dimensionless constant A_γ is given by

$$A_\gamma = \left(\frac{F(E_{\gamma 2})}{\Phi_{SSC}(\epsilon_{\gamma 2})} \right) \left(\frac{TeV}{E_{\gamma 2}} \right)^{-\alpha+3} e^{\tau_{p\gamma}(E_{\gamma 2}, z)}. \quad (15)$$

Comparing Eqs. (11) and (14), the intrinsic flux F_{int} is given as

$$F_{int}(E_\gamma) = A_\gamma \Phi_{SSC}(\epsilon_\gamma) \left(\frac{E_\gamma}{TeV} \right)^{-\alpha+3}. \quad (16)$$

Using Eq. (14), we can calculate the EBL corrected multi-TeV flux where A_γ can be fixed from observed flare data. We can calculate the Fermi accelerated high energy proton flux F_p from the TeV γ -ray flux through the relation[28]

$$F_p(E_p) = 7.5 \times \frac{F_\gamma(E_\gamma)}{\tau_{p\gamma}(E_p)}. \quad (17)$$

The optical depth $\tau_{p\gamma}$ is given in Eq.(5). For the observed highest energy γ -ray E_γ corresponding to a proton energy E_p , the proton flux $F_p(E_p)$ will be always smaller than the Eddington flux F_{Edd} . This condition puts a lower limit on the optical depth of the process and is given by

$$\tau_{p\gamma}(E_p) > 7.5 \times \frac{F_\gamma(E_\gamma)}{F_{Edd}}. \quad (18)$$

From the comparison of different times scales and from Eq.(18) we will be able to constraint the seed photon density in the inner jet region.

IV. RESULTS

The average broadband SED of Mrk 501 is modeled using the standard one-zone leptonic model[25]. The emission takes place from a spherical blob of size R'_b which moves down the conical jet with a bulk Lorentz factor Γ and a Doppler factor \mathcal{D} . The emission region is filled with an isotropic and non-thermal population of electrons and a randomly oriented magnetic field B' . To interpret the VHE flare of May 1, 2009, we use the model parameters of the

TABLE I. These parameters (up to B') are taken from the one-zone synchrotron model of ref. [25] which are used to fit the SED of Mrk 421. The last two parameters are obtained from the best fit to the observed Whipple high state flare data in our model.

Parameter	Description	Value
M_{BH}	Black hole mass[31]	$(0.9 - 3.5) \times 10^9 M_\odot$
z	Redshift	0.034
Γ	Bulk Lorentz Factor	12
\mathcal{D}	Doppler Factor	12
R'_b	Blob Radius	$1.2 \times 10^{16} \text{cm}$
B'	Magnetic Field	0.03 G
R'_f	Inner blob Radius	$5 \times 10^{15} \text{cm}$
α	Spectral index	2.4

one-zone leptonic model which fits reasonably well the average SED and the parameters are shown in Table I.

The observed VHE flare of May 1, 2009 by Whipple telescope was in the range $\sim 317 \text{ GeV} \leq E_\gamma \leq 5 \text{ TeV}$. In the context of photohadronic scenario, this range of E_γ corresponds to the Fermi accelerated proton energy in the range $3.2 \text{ TeV} \leq E_p \leq 50 \text{ TeV}$. So protons in this energy range will interact with the background SSC photons in the energy range $13.6 \text{ MeV} (3.29 \times 10^{21} \text{ Hz}) \geq \epsilon_\gamma \geq 0.86 \text{ MeV} (2.1 \times 10^{20} \text{ Hz})$ to produce the Δ -resonance and subsequent decay of it will produce both γ -rays and neutrinos through neutral and charged pion decay. Also the above range of ϵ_γ lies in the beginning of the SSC spectrum and in this range of energy the sensitivity of the currently operating instruments are not good enough to detect Mrk 501. However, from the multiwavelength campaign the average SED is fitted very well (Fig. 1) and we use this low energy flux in the photohadronic model to calculate the observed flux. Also to account for the contribution of the EBL on the multi-TeV photons we consider the EBL model by Dominguez et al. The EBL models of Dominguez et al.[30] and Franceschini et al.[32] are widely used to constraint the imprint of EBL on the propagation of VHE γ -rays by Imaging Atmospheric Cherenkov Telescopes (IACTs). The normalization constant A_γ given in Eq. (15) can be calculated from the observed flare data.

FIG. 1. The average SED of Mrk 501 is shown in all the energy bands which are taken from Ref. [25]. The SED of low state (MJD 54936-54951; blue squares) and high state (MJD 54952-55; red circles) of the 3-week period are shown. The leptonic model fit to the low state (blue curve) and high state (red curve) are also shown. The blue dotted curve corresponds to the optical emission from the host galaxy. The black curve is the photohadronic fit to the Whipple very high state data (red circles).

The multi-TeV flaring from blazars have an exponential fall which is conventionally modeled as shown in Eq. (1). The cut-off energy E_c is a free parameter and depends on some unknown mechanism. On the other hand, the diffuse background radiation also attenuate the high energy γ -rays as a consequence of the lepton pair production. In the local Universe EBL effect is assumed to be very small. So in most of the flux calculation from the sources in the local Universe, the EBL correction is neglected. However, here instead of the additional exponential cut-off, we take into account the effect of EBL to deplete the intrinsic VHE flux. A very good fit to the Whipple very high state data of May 1 is obtained for $\alpha = 2.4$ and $A_\gamma = 89$ where the EBL corrected flux is considered. We observed that the EBL correction to the VHE γ -ray is small but not insignificant (black curve in Fig. 2) and above 10 TeV it has a faster fall. We have also shown the intrinsic flux (red curve in Fig. 2) to demonstrate the difference. For comparison we have fitted the data with an exponential cut-off function

FIG. 2. The black curve is the hadronic model fit to the Whipple very high state flare data (red filled circles) of Mrk 501 and the red continuous curve is the intrinsic flux in the same model. For comparison we have also shown the Whipple fit to the data (dashed curve) and the exponential fit (dashed dotted curve).

(dashed dotted curve) and the best fit is obtained for $\alpha = 2.6$, $E_c = 30$ TeV and $A_\gamma = 66$. Also we have shown the Whipple fit (dashed curve) for comparison, where it is fitted by the function $dN_\gamma/dE_\gamma = 9.1 \times 10^{-7} (E_\gamma/1\text{TeV})^{-2.1} \text{ph m}^{-2} \text{s}^{-1} \text{TeV}^{-1}$. It is observed that the very high state data of Whipple fits very well with above three scenarios and all are same. However, above 5 TeV, both the EBL corrected fit and the exponential fit differ from the Whipple fit. Again the EBL fit and the exponential fit differ above 10 TeV and the former one falls faster than the latter as can be seen from Fig. 2. Even though all these fit very well with the Whipple very high state data, we observe deviation in the VHE limit. So observation of the VHE flux above 10 TeV will be a good test to constraint the EBL effect on the propagation of VHE γ -rays. In Fig. 1, we also plotted the Whipple very high state data and our model fit (black curve) along with the complete SED.

The high energy protons will be accompanied by high energy electrons and these electrons will emit synchrotron photons in the energy range $\sim 10^{19} \text{ Hz}$ to $\sim 10^{23} \text{ Hz}$ when encountering the magnetic field of the jet. This energy range photons lie in between the high energy

end of the synchrotron spectrum and the low energy tail of the SSC spectrum, thus may not be observed due to their low flux in this region. These high energy electrons will also emit SSC photons and their energy is given by $E_{IC} \sim \gamma_e^2 \epsilon_{syn}$.

As discussed before, in the flaring state, in general, the flux of the two opposing jets can be as high as $F_{Edd}/2$. However, the highest energy protons with $E_p = 50$ TeV must have a flux $F_p < F_{Edd}/2 \simeq 0.8 \times 10^{-7} \text{ erg cm}^{-2} \text{ s}^{-1}$. This constraint translates into $\tau_{p\gamma} > 0.04$ which corresponds to $n'_{\gamma,f} > 1.5 \times 10^{10} \text{ cm}^{-3}$ in the inner jet. However, the hidden jet lies between R_s (Schwarzschild radius) and R'_b . As one representative value we take $R'_f \simeq 5 \times 10^{15}$. From Eq.(6) the seed photon density for $\epsilon_\gamma = 0.86$ MeV satisfies the inequality $n'_{\gamma,f} < 5.1 \times 10^{10} \text{ cm}^{-3}$ which translates to the optical depth to be constrained as $\tau_{p\gamma} < 0.13$. So the optical depth lie in the range $0.04 < \tau_{p\gamma} < 0.13$ and this corresponds to the range of photon density in the inner jet region as $1.5 \times 10^{10} \text{ cm}^{-3} < n'_{\gamma,f} < 5.1 \times 10^{10} \text{ cm}^{-3}$, which shows that the photon density in this region is high. Due to the adiabatic expansion of the inner blob, the photon density will be reduced to n'_γ and also the optical depth $\tau_{p\gamma} \ll 1$. The energy will dissipate once these photons cross into the bigger outer cone. This will drastically reduce the Δ -resonance production efficiency from the $p\gamma$ process.

V. CONCLUSIONS

The VHE flare of May 1, 2009 observed by Whipple telescopes can be explained very well through photohadronic model supplemented with the EBL correction. Previously, the decay of the VHE flare can be explained through the exponential fall of the flux which introduces an additional free parameter, the cut-off energy. However, here, the EBL corrected VHE flux automatically falls exponentially without any additional free parameter and fits very well with the Whipple very high state data. For comparison we have also shown the Whipple fit as well as the exponential fit. All these three curves fit very well with the VHE flare data. However, we have shown that their behaviors differ in the high energy limit. Observation of flare events above 10 TeV will be able to constraint different models and also shed more light on the EBL contribution to the propagation of VHE γ -rays in the local Universe.
